Abstract

Emissions of reactive nitrogen as ammonia (NH₃) and nitrogen oxides (NO_x), together with sulfur dioxide (SO₂), contribute to formation of secondary PM_{2.5} in the atmosphere. Satellite observations of atmospheric NH₃, NO₂, and SO₂ levels since the 2000s provide valuable information to constrain the spatial and temporal variability of their emissions. Here we present a bottom-up Chinese NH₃ emission inventory combined with top-down estimates of Chinese NO_x and SO₂ emissions using ozone monitoring instrument satellite observations, aiming to quantify the interannual variations of reactive nitrogen emissions in China and their contributions to PM_{2.5} air pollution over 2005–2015. We find small interannual changes in the total Chinese anthropogenic NH₃ emissions during 2005–2016 (12.0–13.3 Tg with over 85% from agricultural sources), but large interannual change in top-down Chinese NO_x and SO₂ emissions. Chinese NO_x emissions peaked around 2011 and declined by 22% during 2011–2015, and Chinese SO₂ emissions declined by 55% in 2015 relative to that in 2007. Using the GEOS-Chem chemical transport model simulations, we find that rising atmospheric NH₃ levels in eastern China since 2011 as observed by infrared atmospheric sounding interferometer and atmospheric infrared sounder satellites are mainly driven by rapid reductions in SO₂ emissions. The 2011–2015 Chinese NO_x emission reductions have decreased regional annual mean PM_{2.5} by 2.3–3.8 μg m⁻³. Interannual PM_{2.5} changes due to NH₃ emission changes are relatively small, but further control of agricultural NH₃ emissions can be effective for PM_{2.5} pollution mitigation in eastern China.

1. Introduction

Nitrogen (N) is an essential element for life, but most N in the Earth cannot be used directly by ecosystems. The productivity of the ecosystem depends on the

abundance of reactive N (Nr or fixed N) (Vitousek *et al* 2002). Excessive reactive N will, however, induce negative environmental effects, such as causing soil acidification, eutrophication, decreasing the diversity of ecosystems (Galloway 2001, Galloway *et al* 2003),

and increasing nitric oxide (NO) and nitrous oxide (N₂O) emissions contributing to air pollution and global warming (Pilegaard *et al* 2006, Eickenscheidt *et al* 2011). China is one of the regions with the most intensive reactive nitrogen emissions in the globe due to its rapid industrialization, urbanization, as well as high demand for food production (Liu *et al* 2013). Recent satellite observations have recorded significant changes in atmospheric ammonia (NH₃) and nitrogen dioxide (NO₂) levels over China since the 2000s (Qu *et al* 2017, van der A *et al* 2017, Warner *et al* 2017, Liu *et al* 2018a). Here we will use these satellite observations to constrain Nr emissions in China over 2005–2015 and to assess their impacts on the PM_{2.5} air quality.

Emissions of Nr to the atmosphere are mainly in the forms of NH₃ and nitrogen oxides (NO_x = NO + NO₂). NH₃ is the most abundant alkaline gas in the atmosphere. Over 85% of NH₃ is emitted from agricultural activities (Huang *et al* 2012, Paulot *et al* 2014, Zhang *et al* 2018), including nitrogen fertilizer application to farmland (Sha *et al* 2021) and livestock husbandry systems (Bai *et al* 2016). Chemical industry, residential, human wastes, and traffic are other important anthropogenic sources (Kean and Harley 2000, Sun *et al* 2017). NH₃ can also be released from rewetting processes of natural soils (Hickman *et al* 2018). NO_x is mainly emitted as a byproduct of combustion at high temperature, such as from industry and transportation sectors. Soil and lightening are natural sources of NO_x (Boersma *et al* 2005, Ciais *et al* 2014). Both NH₃ and NO_x are precursors of secondary aerosols. NH₃ in the atmosphere reacts with sulfuric acid (H₂SO₄; produced from the oxidation of SO₂) and nitric acid (HNO₃; produced from the oxidation of NO_x) to form ammonium sulfate and ammonium nitrate aerosols.

Previous studies have shown that the SNA (sulfate–nitrate–ammonium) aerosols account for 20%–57% of PM_{2.5} (particulate matter with an aerodynamic diameter less than 2.5 μm) in Chinese cities (Wang *et al* 2011, Huang *et al* 2014, Liu *et al* 2018b). Changes in Nr and SO₂ emissions can thus strongly affect the SNA fraction of PM_{2.5}. Surface measurements have recorded large decreases in sulfate aerosol concentrations and weak decreases or even increases in nitrate aerosol levels over North China in recent years (Li *et al* 2019a, Zhai *et al* 2021), as driven by the recent clean air actions targeting emissions of SO₂, NO_x, and primary aerosols (Zheng *et al* 2018, Zhang *et al* 2019). NH₃ emissions have not been effectively regulated so far in China, and they have drawn increasing attentions for understanding their mitigation potentials and impacts on PM_{2.5} air pollution (Liu *et al* 2019, Liu *et al* 2021, Guo *et al* 2020). For example, Liu *et al* (2019) reported that 50% NH₃ emission reductions combined with 15% reductions of SO₂ and NO_x emissions could remove 11%–17% of the total PM_{2.5} in China. Here we aim to understand

how interannual variations of Chinese NH₃ emissions might have contributed to changes in PM_{2.5} concentrations over China in the recent past.

In this work, we extend our bottom-up estimates of Chinese NH₃ emissions (Zhang *et al* 2018) to the years 2005–2016, and we evaluate the GEOS-Chem model simulated atmospheric NH₃ concentrations against satellite NH₃ observations. Satellite observations of NO₂ and SO₂ columns are also applied to constrain the interannual variations of Chinese NO_x and SO₂ emissions over this time period (2005–2015). We further quantify the changes of PM_{2.5} concentrations in China contributed by the interannual changes in anthropogenic NH₃, NO_x, and SO₂ emissions, respectively, over 2005–2015 using the GEOS-Chem model simulations.

2. Model description and observations

2.1. The GEOS-chem model

Here we use GEOS-Chem v12.1.1 (<http://acmg.seas.harvard.edu/geos/>), a three-dimensional global chemical transport model to simulate the chemical and physical processes of Nr in the atmosphere from 2005 to 2015 in China. The model is driven by the MERRA-2 assimilated meteorological data provided by the Global Modeling and Assimilation Office at the National Aeronautics and Space Administration (NASA). Meteorology fields such as temperature, relative and specific humidity, vertical pressure velocity, and surface pressure have a temporal resolution of 3 h, and sea level pressure, tropopause pressure, and other surface variables are at 1 h resolution. The model has 47 vertical layers from surface to 0.01 hPa, and the lowest layer is centered at 58 m above sea level.

GEOS-Chem simulates a detailed tropospheric O₃–NO_x–hydrocarbon–aerosol–halogen chemistry as described by Park *et al* (2004) and Mao *et al* (2010). The chemistry system fully couples the H₂SO₄–HNO₃–NH₃ inorganic aerosol thermodynamics system from the ISORROPIA-II thermodynamical model (Fountoukis and Nenes 2007). NH₃ preferably reacts with sulfuric acid to form ammonium bisulfate and ammonium sulfate, then excessive NH₃ would combine with nitric acid to form ammonium nitrate (Binkowski and Roselle 2003). NO_x is also a precursor tropospheric ozone, affecting atmospheric oxidizing capacity and the formation of secondary organic aerosols (SOA). In this study we do not analyze SOA, and focus on the SNA components that are directly related to Nr emissions. Both Nr gases and aerosols deposit to the surface via wet deposition (convective scavenging and largescale precipitation) following the parameterization of Liu *et al* (2001) and dry deposition using a standard resistance-in-series model (Wesely 1989, Zhang *et al* 2001). The GEOS-Chem model simulation of Nr concentrations and deposition over China have been evaluated in a number of previous studies (Wang *et al* 2013, Zhang *et al* 2015, Zhang *et al* 2016,

Zhao *et al* 2015, Shao *et al* 2019, Lu *et al* 2021, Zhai *et al* 2021).

Emissions in GEOS-Chem v12.1.1 are processed through HEMCO (Harvard–NASA Emission Component) (Keller *et al* 2014). We used the Community Emissions Data System (Hoesly *et al* 2018) for global anthropogenic emissions, overwritten by regional emissions inventories including 2011 NEI (National Emissions Inventory) from EPA (United States Environmental Protection Agency) for US (NEI-2011), EMEP (European Monitoring and Evaluation Programme; www.emep.int/index.html) emissions over Europe, and Canada's Air Pollutant Emissions Inventory. Emissions over Asia are overwritten by the MIX inventory (Li *et al* 2017) that includes the MEIC inventory (Multi-resolution Emission Inventory for China; <http://meicmodel.org/>) over China except for NH_3 , NO_x , and SO_2 emissions in China as will be described below. Natural NO_x sources from soil and lightning are also included (Lu *et al* 2021).

In this study we have conducted four sets of GEOS-Chem model simulations for 2005–2015 at the global 2° latitudes by 2.5° longitude resolution. The standard simulation (BASE) uses the emission setting as described above that accounts for the interannual variations of Chinese Nr and SO_2 anthropogenic emissions. Three sets of sensitivity simulations by fixing the Chinese anthropogenic NH_3 , Nr ($\text{NH}_3 + \text{NO}_x$), and additionally SO_2 ($\text{Nr} + \text{SO}_2$) emissions, respectively, to the year 2005 are conducted (i.e. Fix NH_3 , Fix Nr , and FixALL), and their differences with the BASE simulation and with each other estimate the impacts from their emissions' interannual variations. For better evaluating the model results, we have also conducted a nested GEOS-Chem simulation using the BASE emission conditions for the years 2005–2015 at a higher 0.5° latitude $\times$ 0.625° longitude resolution over Asia and 2° latitudes $\times$ 2.5° longitude for the rest of the world. All the simulations are initiated after one year spin-up.

2.2. Observations

We have compiled an ensemble of surface and satellite observations to evaluate our estimates of Nr emissions and resulting model simulations. We use observed surface NH_3 concentration data at 53 sites for 2015 over China from AMoN-China (Pan *et al* 2018), measurements of sulfate, nitrate and ammonium aerosol concentrations from CAWNET (Zhang *et al* 2012) over 2006–2007 and from Zhang *et al* (2019) over 2013–2015. We also use wet deposition observations of ammonium and nitrate, including 57 sites from EANET from 2005 to 2015 (EANET 2005–2015), ten sites from the Regional Atmospheric Deposition Observation Network on the North China Plain (Pan *et al* 2012) during 2008–2010, and 43 sites from the Nationwide Nitrogen Deposition Monitoring Network (Xu *et al* 2015) during 2010–2012.

We use satellite observations of atmospheric NH_3 concentrations from the infrared atmospheric sounding interferometer (IASI) and the atmospheric infrared sounder (AIRS). IASI is passive infrared Fourier transform spectrometer aboard the MetOp-A satellite in a polar sun-synchronous orbit with equator crossing local time of 09:30 in the morning and 21:30 at night (Van Damme *et al* 2014). Here we use the level 2 dataset of Artificial Neural Network for IASI- NH_3 -v2.2 R-I (Van Damme *et al* 2017). Morning observations have lower relative errors than those at night, so that we only use morning data with relative errors less than 100%, and then apply the relative error weighted mean method (Van Damme *et al* 2014) to compute monthly mean observations on a 0.25° latitude $\times$ 0.25° longitude grid over 2008–2015. The AIRS instrument aboard the NASA's Aqua satellite platform provides atmospheric NH_3 retrievals since 2002 (Warner *et al* 2016). Here we use the AIRS NH_3 data at 918 hPa where the retrieval sensitivity peaks from September 2002 to August 2016 over China as presented by Warner *et al* (2016), Warner *et al* (2017).

We also use satellite observations of NO_2 and SO_2 columns from the ozone monitoring instrument (OMI). OMI aboard the NASA's Aura satellite launched in 2004 measures backscattered solar radiation with a nadir-scanning resolution of $13 \times 24 \text{ km}^2$ and at local passing time of 13:45 (Levelt *et al* 2006). We use the NASA standard products of daily Level-3 NO_2 tropospheric column (Krotkov *et al* 2019; https://disc.gsfc.nasa.gov/datasets/OMNO2d_003/summary?keywords=TROPOMI%20NO2) and SO_2 planetary boundary layer (PBL) column (Li *et al* 2020; https://disc.gsfc.nasa.gov/datasets/OMSO2e_003/summary?keywords=OMSO2e) for the period of 2005–2015. Both products have a spatial resolution of $0.25^\circ \times 0.25^\circ$, and are regridded to the model $2^\circ \times 2.5^\circ$ resolution.

We further evaluate the model simulated surface $\text{PM}_{2.5}$ concentrations with available $\text{PM}_{2.5}$ datasets. We use the nationwide $\text{PM}_{2.5}$ surface measurements for 2013–2015 obtained from the China National Environmental Monitoring Center (CNEMC; <https://air.cnemc.cn:18007/>). Ground-level $\text{PM}_{2.5}$ products derived from satellite observations of aerosol optical depth over 2005–2015 are also applied (Hammer *et al* 2020; <https://sites.wustl.edu/acag/datasets/surface-pm2-5/#V4.CH.03>). The products have a spatial resolution of $0.1^\circ \times 0.1^\circ$ and are regridded to $0.5^\circ \times 0.625^\circ$.

In addition, the land cover datasets retrieved from the moderate resolution imaging spectroradiometer (MODIS) aboard the Terra and Aqua satellites are applied to identify the changes of cropland distributions in China. We use the Terra-Aqua combined land cover product (MCD12Q1) (<https://modis-land.gsfc.nasa.gov/landcover.html>), in which

the types of land cover at 500 m resolution are identified to 17 classes, including 11 natural vegetation classes, three human-altered classes, and three non-vegetated classes. We extract the grids classified as cropland and calculate the cropland areas at the model $0.5^\circ \times 0.625^\circ$ resolution. The MCD12Q1 products covers the period of 2005–2012, and the latest available year 2012 data is applied to the years afterwards in this study.

3. Results and discussion

3.1. Estimates of Chinese NH_3 emissions over 2005–2016

Previously we have developed a bottom-up inventory of Chinese agricultural NH_3 emissions for the year 2008 (Zhang *et al* 2018). Here we extend the bottom-up estimates of Chinese agricultural NH_3 emissions to 2005–2016. Details of the bottom-up method can be found in Zhang *et al* (2018). Below we provide a brief summary and describe our improvements for estimating the interannual variations of Chinese NH_3 emissions over 2005–2016.

The NH_3 emissions from fertilizer use are based on practical fertilizer application information, including cropland area, fertilizer application timing and rate for 21 types of crops, vegetables, and fruits. Emission factors are calculated as a function of fertilizer type, application mode, soil pH, and soil cation exchange capacity, and further modulated by local surface temperature and wind speed. We previously used a baseline cropland area for the year 2000 (Zhang *et al* 2018). Here we scale the baseline cropland area to match those observed by MODIS as described in the section above to account for their interannual changes in China. The fertilizer application amount and types have also changed substantially during this period. We use the year-specific statistics of provincial fertilizer application amounts from the China Rural Statistical Yearbook (National Bureau of Statistics (NBSC) 2006–2017), and associated changes in the fractions of synthetic fertilizer types are estimated by the International Fertilizer Association (www.fertilizer.org).

NH_3 emissions from livestock account for six categories of animals, including beef cattle, dairy cows, goat, sheep, pig, and poultry raised in three raising systems: free-range, intensive, and grazing (Zhang *et al* 2018). The most common system in the rural area is free-range, which is the traditional way to raise livestock leading to large NH_3 emissions. The intensive raising system becomes the most popular way near megacities due to its high efficiency and easiness to manage the shelter environment. Grazing mostly occurs in Northwest China. We use the livestock manure mass-flow methodology and emission factors from Huang *et al* (2012), and further consider the meteorology conditions (2 m air temperature and

10 m wind speed) effects on emission factors (Zhang *et al* 2018). The numbers of animals raised in intensive and grazing systems of each province are divided based on the Chinese Animal Husbandry and Veterinary Yearbook (Editorial Committee of China animal husbandry and veterinary Yearbook 2006–2017).

In addition to the agricultural sources, we also include NH_3 emitted from vehicles, biomass burning, residential burning, industry, and waste disposal estimated by Kang *et al* (2016) from 2005 to 2012. To further account for changes in some of these sources over 2013–2016, we assume that NH_3 emissions from vehicle, industry, and residential burning follow the same interannual variations as SO_2 emissions for each source, and apply the corresponding SO_2 emission changes estimated from the MEIC inventory.

Figure 1 shows the spatial distribution of anthropogenic NH_3 emissions over China for the year 2015, and interannual changes in Chinese NH_3 emissions from different sources over 2005–2016. High NH_3 emissions can be found in the eastern China, in particular, over the key regions such as the North China Plain (including Beijing–Tianjin–Hebei (BTH) and surrounding areas), Yangtze River Delta (YRD), Pearl River Delta (PRD), and Sichuan Basin (SCB) (see figure S1 available online at stacks.iop.org/ERL/16/125004/mmedia for their locations). These regions are highly populated and also have intense agricultural activities. The annual total Chinese anthropogenic NH_3 emissions are 12.5 Tg NH_3 in 2015, and range from 12.0–13.3 Tg during 2005–2016, with 37%–42% from fertilizer application and 46%–53% from livestock manure management. The national total NH_3 emissions show relative weak interannual variations, while spatially they generally increase in western China and decrease in eastern China relative to 2005 for both the fertilizer application and livestock sources (figure S2). The increases of NH_3 emissions in western China are largely driven by increasing fertilizer application amount and livestock number, different from those in eastern China and national totals as discussed below.

We find that the national total NH_3 emissions from fertilizer applications are about 5.0 Tg in 2005, increase to 5.3 Tg in 2012, then decrease to 4.5 Tg in 2016 (figure 1). The trend is different from that for the national synthetic fertilizer application amounts, which increase from 24.2 Tg N in 2005 to 27.1 Tg N in 2014, and then decrease to 26.3 Tg N in 2016. Differences in trends of fertilizer use and fertilizer NH_3 can be mainly attributed to the switch of fertilizer type from ammonium bicarbonate (ABC) to urea and compound fertilizer with the latter have lower emission factors (figure S3) as also pointed out by Kang *et al* (2016) and Adalibieke *et al* (2021). NH_3 emissions from livestock are 6.0 Tg in China over 2005–2016, reaching 7.0 Tg in 2005 then dropping to 5.8 Tg in 2007 due to diseases among pigs and increased

costs to raise cattle. The livestock NH_3 emissions then remained nearly unchanged from 2007 to 2016, although the livestock numbers have increased over this time period, due to a shift of raising systems from free-range to large intensive systems since 2007 (figure S3). Figure 1 also compares our estimates of Chinese NH_3 emissions estimates with emission estimates in previous studies. Our results are well in the range of the existing inventories, and the interannual variations are similar to estimates of Kang *et al* (2016) and MEIC (Zheng *et al* 2018).

3.2. Top-down estimates of Chinese NO_x and SO_2 emissions during 2005–2015

We use OMI satellite observations of NO_2 tropospheric columns and SO_2 PBL columns to constrain the interannual variations of NO_x and SO_2 emissions in China over the period of 2005–2015. We follow the finite-difference mass-balance inversion method from Geddes and Martin (2017). We have conducted two sets of 11 year (2005–2015) GEOS-Chem simulations at the $2^\circ \times 2.5^\circ$ resolution: one with the Chinese SO_2 and NO_x emissions fixed to

Figure 2. Satellite observations of annual mean NO₂ tropospheric columns (top two rows) and SO₂ PBL columns (bottom two rows) from the OMI instrument in the years 2005, 2007, 2010, 2011, 2013, and 2015 over China.

those from the MEIC inventory in the year 2010, and the other applies +30% perturbations on the Chinese SO₂ and NO_x emissions based on the first simulation setup. We then calculate the changes in simulated NO₂ tropospheric columns and SO₂ PBL columns, and estimate the interannual variations of their emissions for years 2005–2015 using the formula below

$$E_{\text{topdown}} = E_{\text{prior}} \times \left(1 + \frac{\Delta E}{E_{\text{prior}}} \times \frac{\Omega_{\text{prior}}}{\Delta \Omega} \times \frac{\Omega_{\text{sat}} - \Omega_{\text{prior}}}{\Omega_{\text{prior}}} \right). \quad (1)$$

where E_{topdown} is the top-down SO₂ or NO_x emissions; E_{prior} is prior SO₂ or NO_x emissions based on the 2010 MEIC estimates; ΔE is 30% perturbation of E_{prior} ; Ω_{prior} is simulated SO₂ or NO_x columns with prior emissions; $\Delta \Omega$ is simulated changes of SO₂ or NO_x columns between prior and 30% perturbation emissions; Ω_{sat} is SO₂ or NO_x columns observed from OMI. The top-down emissions are calculated monthly and then integrated to annual totals. Here we use the MEIC SO₂ and NO_x emissions for the year 2010 as the base conditions, and apply the satellite

derived interannual variability over 2005–2015 at each model grid in order to avoid any systematic bias in the satellite observations (Lamsal *et al* 2011, Cooper *et al* 2017, Geddes and Martin 2017).

Figure 2 shows the OMI satellite observations of NO₂ and SO₂ over China in selected 6 years during 2005–2015. Large interannual variations can be seen from these satellite observations, indicating rapid economic development as well as the implementation of emission control measures in China over the time period. Such interannual variations are reflected in the top-down estimates of Chinese NO_x and SO₂ emissions. Figure 1 also shows the spatial distributions of the top-down Chinese NO_x (as NO) and SO₂ emissions in 2015 and interannual variations of national totals over 2005–2015 in the context of comparisons with other previous studies. We can see that, according to the OMI satellite observations, NO_x emissions (as NO) have increased from 14.7 Tg in 2005 to 20.4 Tg in 2011, and then decreased to 15.8 Tg in 2015. The interannual variability of top-down NO_x emissions are similar to that from the MEIC estimates, although MEIC suggests a later peaking year

and slightly higher emission in 2012 than 2011. The previous studies such as Liu *et al* (2016) and Qu *et al* (2017) also identified that Chinese NO_x emissions peaked in 2011 and declined by 21% over 2011–2015 by combining OMI satellite observations and emission inventories. This is consistent with our analysis of 22% NO_x emission reduction over 2011–2015, and can be mainly attributed to regulations of power plants and vehicle emissions (Liu *et al* 2016). Over the whole period NO_x emissions in China still show an increase of 1.1 Tg (7.5%) in 2015 relative to 2005.

The Chinese SO_2 emission reductions have occurred earlier due to the application of flue-gas desulfurization devices in power plants since 2006 (Lu *et al* 2010). Our top-down estimates show that Chinese SO_2 emissions are 46.3 Tg in 2007 and then decrease at a rate of about -5.9 Tg yr^{-1} . The small peak in 2011 can be found in other top-down SO_2 emission studies (Koukouli *et al* 2018, Qu *et al* 2019), although our estimates show a much larger interannual variability. The peaks of top-down Chinese SO_2 emissions in the years 2007 and 2011 mainly reflect the high SO_2 columns observed from OMI in the two years as can be seen in figure 2. Overall we estimate that SO_2 emissions in China have decreased from 37.4 Tg in 2005 to 21.0 Tg in 2015 (-43.8%); the trends are similar to the MEIC estimates (Zheng *et al* 2018). It should be noted that the top-down inferred NO_2 and SO_2 interannual changes are subject to uncertainties in the OMI retrievals, such as the reduced spatial coverage due to OMI row anomaly since 2007. The OMI products used in this study also treat aerosols implicitly in the retrieval algorithm, which may affect the observed interannual variations over polluted regions with changing aerosol levels (Lin *et al* 2015, Lamsal *et al* 2021).

3.3. Impacts of interannual variations of Nr emissions

Figures S4–S7 evaluate the BASE simulation with the ensemble of measurements as described above. The BASE model in general reproduces the measured near surface NH_3 concentrations and nitrogen (NH_4^+ and NO_3^-) wet deposition fluxes with correlation coefficients of 0.51–0.82 and normalized mean biases (NMBs) within 30%. The model results underestimate the measured NH_3 concentrations and NH_4^+ wet deposition fluxes in summer by 41.9% (2015) and 25.0% (2008–2012 average), respectively, likely reflecting that our estimates of Chinese NH_3 emissions in summer are still biased low. The BASE model results are also in good agreement with the measured surface SNA aerosol concentrations (figure S6). Further evaluations of the model simulated surface $\text{PM}_{2.5}$ concentrations with CNEMC measurements and satellite products show consistent spatial distributions in eastern China (figure S7).

Figure 3 shows the IASI satellite observed spatial distribution of atmospheric NH_3 columns and the

corresponding model results averaged over 2008–2015. The comparison of IASI observations and model results shows a high spatial correlation coefficient of 0.82. The model captures the observed high NH_3 levels over North China, while there is an overall low bias of -35.6% relative to the IASI observations, as can be seen from the comparisons over the southern China and western China. In addition to the possible low bias in the NH_3 emission estimates, IASI NH_3 measurements may also be biased high due to the relative error weighted method, which tends to give more weight to high values (Van Damme *et al* 2015). We also compare the simulated monthly mean NH_3 concentrations in January, April, July and October 2005–2015 with AIRS observations at 918 hPa (Warner *et al* 2017) in figure S8. AIRS NH_3 observations mainly cover the intense agricultural regions of China. We find that compared with the AIRS observations, the seasonal variations of simulated NH_3 concentrations in China are consistent with a high correlation coefficient (0.85) and a small low bias (-5.5%).

Figure 3 also compares IASI observed and model simulated 2008–2015 interannual variations of NH_3 columns over the four most densely populated Chinese regions: BTH, YRD, PRD, and SCB. Despite the small interannual variations and decreases since 2012 in the Chinese NH_3 emissions (figure 1), both IASI satellite observations and model results show increases in atmospheric NH_3 concentrations since 2011 over the four regions. The BASE model results well capture the IASI observed NH_3 interannual variation over these regions, although there are considerable underestimates ($-43\% \sim -47\%$) of NH_3 concentrations over YRD and SCB. Previous studies have reported the increases in atmospheric NH_3 over the North China (i.e. BTH and surrounding areas) observed by IASI and AIRS, and mainly attributed such NH_3 increases to SO_2 emission reductions (Warner *et al* 2017, Liu *et al* 2018a). Here we use our sensitivity simulations (section 2.1) to identify drivers of NH_3 interannual variations over broader regions of China. We find that over the four regions SO_2 emission reductions are the dominant factor driving the NH_3 concentration increases (figure S9). Decreases in NO_x emissions since 2011 also show small contributions over BTH and YRD. As explained by Liu *et al* (2018a), reductions in SO_2 and NO_x emissions would lower the formation of SNA and thus enhance the NH_3 gas-phase partitioning. Changes in the NH_3 concentration are generally weak except for the sudden drop from 2006 to 2007 over BTH, consistent with the changes in NH_3 emissions (figure 1).

We now quantify the changes in $\text{PM}_{2.5}$ air pollution attributable to the interannual changes in NH_3 , NO_x , and SO_2 emissions over China. Figure 4 shows the simulated seasonal and annual mean surface SNA aerosol concentrations over China for the year 2015, and also their changes due to the changes in Chinese

Figure 3. Spatial distributions of 2008–2015 annual mean NH_3 columns over China as (a) observed by the IASI satellite instrument, (b) corresponding model results, and (c) their scatter-plots with the NMB and the correlation coefficient (r) shown inset. The bottom panels show IASI observed (black lines) and model simulated (orange lines) annual mean NH_3 columns averaged over four key regions of China: (d) BTH, (e) YRD, (f) PRD, and (g) SCB (see figure S1 for their locations) over 2008–2015.

Figure 4. Model simulated seasonal and annual mean SNA concentrations over China in 2015 (top panels), and their changes in 2015 relative to the year 2005 as driven by changes in Chinese emissions of NH_3 alone (second row), NO_x alone (third row), SO_2 alone (fourth row), and the three emissions jointly (bottom row). The population weighted mean concentrations over China are shown inset. Values are calculated based on model simulations as $\text{VarNH}_3 = \text{BASE} - \text{FixNH}_3$, $\text{VarNO}_x = \text{FixNH}_3 - \text{FixNr}$, $\text{VarSO}_2 = \text{FixNr} - \text{FixALL}$, $\text{VarALL} = \text{BASE} - \text{FixALL}$ described in the text.

NH_3 , NO_x , and SO_2 emissions from 2005 to 2015. We calculate the national population-weighted SNA concentrations and changes using the population dataset of the Gridded Population of the World version 4 (Center for International Earth Science Information Network (CIESIN) Columbia University 2018).

The national mean population-weighted SNA concentrations are $38.3 \mu\text{g m}^{-3}$ annually, peaking in winter ($50.2 \mu\text{g m}^{-3}$) and being the lowest in summer ($28.9 \mu\text{g m}^{-3}$). Such strong seasonal variations are largely caused by the higher pollutants' emissions and more frequent stagnant weather conditions

over eastern China in winter than summer, and more effective removal of air pollution by precipitation in summer than winter as well (Liu *et al* 2018b).

Changes in Chinese NH_3 , NO_x , and SO_2 emissions in 2015 relative to 2005 have led to large changes in the SNA aerosol concentrations. As shown in figure 4, due to the large reductions in SO_2 emissions, the annual mean population weighted SNA aerosol concentrations have reduced by $8.3 \mu\text{g m}^{-3}$. There is a higher reduction of $9.9 \mu\text{g m}^{-3}$ in summer than $6.1 \mu\text{g m}^{-3}$ in winter, reflecting higher efficiency of SO_2 photochemical oxidation to sulfuric acid in summer. Spatially, in the BTH and SCB, the 2005–2015 SO_2 emission reductions can reduce seasonal and annual mean SNA concentrations by more than $20 \mu\text{g m}^{-3}$. Compared to the effects of SO_2 emission reductions, changes in SNA aerosol concentrations due to 2005–2015 NH_3 and NO_x emission changes are weaker. The 2005–2015 reduction of Chinese NH_3 emissions by 0.8 Tg (−6%) lead to $-0.9 \mu\text{g m}^{-3}$ changes in SNA, increases of NO emissions by 1.1 Tg (7.5%) enhance SNA by $1.6 \mu\text{g m}^{-3}$, while changes in Chinese SO_2 emissions by 16.4 Tg (−48.3%) cause $-8.3 \mu\text{g m}^{-3}$ reduction. Thus, percentage changes in Nr emissions have shown similar efficiency affecting $\text{PM}_{2.5}$ air pollution than SO_2 emission changes in China. Together, changes in Nr and SO_2 emissions from 2005 to 2015 could have decreased the annual population weighted $\text{PM}_{2.5}$ by $-7.5 \mu\text{g m}^{-3}$ in China ($-9.7 \mu\text{g m}^{-3}$ in summer and $-5.0 \mu\text{g m}^{-3}$ in winter).

These changes in the SNA aerosol concentration largely reflect the changes of their precursor emissions, but can also be influenced by the changes in atmospheric oxidants affecting the SNA aerosol formation. For example, NO_x emission changes would affect tropospheric ozone concentrations and thus affect the oxidation of SO_2 to form sulfate aerosol. In turn, changes in aerosol levels would also affect ozone concentrations via aerosol chemistry and photolysis pathways (Li *et al* 2019b). Figure S10 shows the simulated changes in seasonal and annual mean surface ozone concentrations over China caused by changes in Chinese NH_3 , NO_x , and SO_2 emissions from 2005 to 2015. Compared with figure 4, the aerosol concentration changes driven by NH_3 and SO_2 emission changes tend to be negatively correlated with the ozone concentration changes, likely reflecting the suppression of ozone formation via aerosol radiative effect or the ozone sink via aerosol chemistry. The increases of NO_x emissions from 2005 to 2015 could also decrease seasonal mean ozone levels due to titration at night and in winter, except in summer when photochemistry is active. Future work is needed to quantify the interaction of interannual changes in SNA aerosol and ozone concentrations.

Analyzing the interannual variations of emission changes (figure S11), we can see strong influences on the regional SNA aerosol concentration from changes

in Chinese NO_x emissions. We estimate that over the study period the Chinese NO_x emissions peak in 2011. Increases in NO_x emissions from 2005 to 2011 increased the annual mean $\text{PM}_{2.5}$ concentrations by $6.5 \mu\text{g m}^{-3}$ in BTH, $4.6 \mu\text{g m}^{-3}$ in YRD, and $2.8 \mu\text{g m}^{-3}$ in SCB, offsetting or even exceeding the $\text{PM}_{2.5}$ decreases due to SO_2 emission reductions. Estimated changes in Nr emissions and their effects on $\text{PM}_{2.5}$ over PRD are small over this period. Reductions in Chinese NO_x emissions after 2011 have accelerated the $\text{PM}_{2.5}$ decreases. The 2011–2015 Chinese NO_x emission reduction reduced regional mean $\text{PM}_{2.5}$ by $3.8 \mu\text{g m}^{-3}$ in BTH, $3.2 \mu\text{g m}^{-3}$ in YRD, and $2.3 \mu\text{g m}^{-3}$ in SCB. Together changes in Chinese Nr and SO_2 emissions over 2011–2015 have decreased the regional mean $\text{PM}_{2.5}$ by $12.5 \mu\text{g m}^{-3}$ in BTH, $8.8 \mu\text{g m}^{-3}$ in YRD, and $9.7 \mu\text{g m}^{-3}$ in SCB, with changes in Nr emissions contributing 20%–36% of the decreases. According to the CNEMC measurements (figure S7), $\text{PM}_{2.5}$ concentrations have decreased rapidly in eastern China since 2013 due to stringent air pollution control actions, e.g. decreased by $\sim 29 \mu\text{g m}^{-3}$ over 2013–2015 in BTH. Our results suggest that $\sim 40\%$ of the decreases can be attributed to changes in Nr and SO_2 emissions over China.

4. Conclusions

We have analyzed the interannual variations of Nr ($\text{NH}_3 + \text{NO}_x$) emissions in China over 2005–2015 and quantified their contributions to $\text{PM}_{2.5}$ air pollution. Satellite observations of NH_3 , NO_2 , and SO_2 atmospheric concentrations during this time period are used to constrain Chinese Nr and SO_2 emissions. We have applied a bottom-up approach to estimate Chinese NH_3 emissions, and a top-down approach for NO_x and SO_2 emission estimates. The bottom-up estimates of NH_3 emissions resolve the interannual variations of agricultural activities such as changes in fertilizer application amounts and types and livestock numbers. We find small interannual changes in the total Chinese anthropogenic NH_3 emissions, ranging 12.0–13.3 Tg during 2005–2016, with 37%–42% from fertilizer application and 46%–53% from livestock manure management. Although fertilizer and livestock amounts have increased over the time period, the shifts of fertilizer types (from ABC to urea and nitrogen compounds) and livestock raising systems (from free-range to intensive systems) keep the total Chinese NH_3 emissions relatively stable or even slightly decreasing after 2012.

In contrast to NH_3 , Chinese NO_x and SO_2 emissions as inferred from the satellite observations show large interannual changes. We estimate that Chinese NO_x emissions (as NO) have increased from 14.7 Tg in 2005 to 20.4 Tg in 2011, and then decreased to 15.8 Tg in 2015. Chinese SO_2 emissions peaked at 46.3 Tg in 2007 and rapidly decreased over 2011–2015, reaching 21.0 Tg in 2015. Based on these

Chinese NH_3 , NO_x , and SO_2 emissions over 2005–2015, the GEOS-Chem model simulation can well capture the increases of atmospheric NH_3 levels after 2011 in eastern China as observed by the IASI satellite observations (although with some low biases in the model results) and attribute the atmospheric NH_3 increases mainly to the rapid SO_2 emission reductions.

We find that interannual variations of Nr and SO_2 emission changes have strongly influenced the regional SNA components of $\text{PM}_{2.5}$ in eastern China over 2005–2015. The Chinese NH_3 emission changes in 2015 relative to 2005 (–6%) lead to $0.9 \mu\text{g m}^{-3}$ reductions in the national population weighted mean SNA concentration, compared with an increase of $1.6 \mu\text{g m}^{-3}$ due to 7.5% NO_x emission increases, and a decrease of $8.3 \mu\text{g m}^{-3}$ due to 48.3% SO_2 emission reductions. The 2011–2015 Chinese NO_x emission reductions decreased regional mean $\text{PM}_{2.5}$ by $2.3\text{--}3.8 \mu\text{g m}^{-3}$, also becoming an important driver of recent $\text{PM}_{2.5}$ air quality improvements. The Chinese air pollution control actions after 2011 have mainly focused on power plant, industry, and transportation sectors that have significantly lowered NO_x and SO_2 emissions (Zheng et al 2018). Our analyses indicate that strengthening agricultural NH_3 emission reduction can achieve similar effectiveness for further improving $\text{PM}_{2.5}$ air quality in eastern China.
